Abstract

The aim of this work was to evaluate the agronomic performance of three-waycross maize hybrids grown in different environments, to determine linear associations and to employ multivariate analysis for the measured traits. The experimental design used was randomized blocks in factorial scheme, arranged in three replicates. The three-way cross maize hybrids evaluated evidence phenotypic variability for the traits spike diameter, spike length, number of rows with grains, number of grains per row, cob mass and spike grains mass. The growing environment of Campos Borges-RS favors the increment of spike diameter, number of grains per row, spike mass, cob diameter, cob mass, mass of a thousand grains, spike grains mass and grain yield. Significant interactions between three-way cross maize hybrids and growing environments are verified for plant height, spike insertion height and prolificity. The traits spike diameter, mass of a thousand grains and mass of grains per spike present positive correlation with maize grain yield. The distinction of three-way cross hybrids is based on spike insertion height, spike diameter, plant height and mass of a thousand grains. The hybrids 2B688 HX® and 2A55 HX® are genetically closer, according to the biometric approach of canonical variables.

Keywords: *Zea mays* L., strategy of breeding, genotype × environment interaction

1. Introduction

Maize (*Zea mays* L.) has an outstanding role in the world agribusiness scenario because it provides many products for human and animal diet, also being used for ethanol production and other branches of industry (Demetrio, 2008). Maize is the second most cultivated crop in the world, with 177 million hectares sown in the 2015/2016 growing season (USDA, 2016). An area of 16.2 million hectares was grown in Brazil during the 2015/2016 agricultural year, with production of 84 million tons of grains, ranking the country as third larger producer of this cereal (USDA, 2016). The southern region produced 31% of the national total, playing important role in the agricultural scenario (CONAB, 2016). Due to the large number of maize genotypes available for farmers, the decision making about which is the most suitable for their economic and technological conditions becomes crucial. Hence, it is necessary to carry out trials of agronomic performance to evaluate the genotypes recommended for specific areas of cultivation, generating trustworthy and useful information for farmers.

There are many genetic bases of maize genotypes available in the market. The single cross hybrids are originated from crossing between two homozygous lineages, enhanced by the specific combining ability and heterosis effects (Nardino et al., 2016; Demari et al., 2016). Single cross hybrids are potentially more productive than the other types of hybrids, however, they demand improved environment and cultural traits. Three-waycrosshybrids results from crossing between a homozygous lineage and a single cross hybrid, being phenotypically uniform, with productive potential intermediate to single and double cross hybrids, however, presenting better adaptability to environment variations due to its greater genetic base, compared to single cross hybrids (Singh et al., 2012).

The double cross hybrids come from the cross between two single cross hybrids, and due to their broad genetic constitution, they present greater stability and lower cost of production (Emygdio et al., 2007).

One of the major obstacles to maize breeding programs is the instability of genotypes behavior due to environmental variations (Szareski et al., 2018). Thus, the comprehension of genotype \times environment interaction ($G \times A$) becomes indispensable for maize breeding and genotypes recommendation (Maia, 2006). Grain yield in maize is determined by the genotype's genetic constitution and its plasticity in different environment conditions. Considering different environments, importance must be given for $G \times E$ interaction (Cruz et al., 2012; Szareski et al., 2017; Carvalho et al., 2017). Growing environment is constituted by meteorological and edaphic elements, and cultural traits, which may differentially influence genotypes behavior (Galon et al., 2010). Grain yield is a complex trait determined by association of several characters and expression of many genes, being highly dependent of environment conditions (Ribeiro, 2012).

In order to comprehend genotypes inconsistencies in different environments, the multivariate analyses are to be employed, which consider the performance of different traits, generating a single tendency (Costa, 2010). These analyses applied in the dynamics of a breeding program may aid to distinguish genotypes more efficiently (Oliboni, 2009). The employment of multivariate techniques allows to comprehend genetic differentiations among genotypes, and to use this information to boost the crop breeding (Hallauer et al., 2010; Uitzil et al., 2016). Therefore, the aim of this work was to evaluate the agronomic performance of three-way cross maize hybrids grown in different environments, to determine linear associations and to employ multivariate analysis for the measured traits.

2. Material and Methods

The experiment was carried out during the 2014/2015 agricultural year, in two growing environments, which are characterized in the Table 1.

Table 1. Characterization of the growing environments regarding geographic coordinates, altitude, soil type and climate

Growing environment	Latitude	Longitude	Altitude (m)	Soil type ¹	Climate ²
Campos Borges, RS	28°52'31" S	53°00'55" O	513	Dark red latosol	Cfa subtropical
Salto do Jacuí, RS	29°5'16" S	53°12'27" O	306	Dark red latosol	Cfa subtropical

Note. ¹ Classification according to methodology proposed by Santos et al. (2006); ² Climatic classification according to Maluf (2000).

The experimental design used was randomized blocks in factorial scheme, being two growing environments (Campos Borges, RS and Salto do Jacuí, RS) \times six three-way cross maize hybrids (DKB566VTPRO[®], 2B339Hx[®], 2A55Hx[®], 2B688Hx[®], AG8011[®], KSP3248[®]), arranged in three replicates. Direct sowing system was used, with base fertilization of 300 kg ha⁻¹ of NPK in the formula 10-20-20. For topdressing, it was used 200 kg ha⁻¹ of urea at V₄ and V₆ vegetative stages (Fancelli & Dourado Neto, 2000). The sowing density for all genotypes was 75,000 plants per hectare. The experimental units were composed by four rows of five meters length, spaced 0.5 meters between rows. The useful plot was composed by two central lines, discarding 0.5 meters of each extremity to minimize border effects. The management of pests and weeds was carried preventively, in order to minimize biotic effects.

The traits of agronomic interest were determined based on the methodology proposed by Carvalho et al. (2014), sampling three plants aleatory in each experimental unity. The evaluated traits were: Plant height (PH), results in centimeters (cm); Spike insertion height (SH), results in meters (m); Spike diameter (SD), results in millimeters (mm); Spike length (SL), results in centimeters (cm); Spike mass (SM), results in grams (g); number of rows with grains in the spike (NRG), results in units; number of grains per row (NGR), results in units; cob diameter (CD), results in millimeters (mm); cob mass (CM), results in grams (g); mass of grains per spike (MGS), results in grams (g); mass of a thousand grains (MTG), results expressed in grams (g); grain yield (GY), results in kg ha⁻¹.

The data was subjected to analysis of variance by the F test at 5% of probability. The variance analysis's assumptions were performed by the Shapiro-Wilk (1965) test in order to reveal the data normality. The homogeneity of residual variances was verified by the Hartley test (Ramalho et al., 2012). The joint analysis of variation sources was performed to reveal interactions between growing environments and three-way-cross-maize

hybrids. In case of interaction, the effects were sliced. Traits that did not reveal significant interaction were sliced for principal effects for each factor through Tukey test at 5% of probability. Posteriorly, it was performed the Pearson's linear correlation analysis for both growing environments in order to reveal the tendency of associations between traits. The next step was to perform the analysis of relative contribution by Singh (1981), and canonical variates (Cruz et al., 2014). All statistical procedures were performed through the Genes software (Cruz, 2013).

3. Results and Discussion

The analysis of variance revealed significant interaction for growing environments \times three-way cross maize hybrids at 5% of probability for plant height (PH), spike insertion height (SH) and prolificity (PRO) (Tables 4, 5 and 6). Evaluating grain yield components of maize hybrids grown in four different environments from southern Brazil, Nardino et al. (2016) found no significant interaction. Paixão (2008) verified significant genotype \times environment interaction for plant height and spike insertion height, evaluating genotypes of broad genetic basis.

Regarding the variation source three-way cross maize hybrids, significant differences were evidenced for the traits spike diameter (DE), spike length (SL), number of rows with grains per spike (NRG), number of grains per row (NGR), cob mass (CM) and mass of grains per spike (MGS) (Table 2).

Table 2. Averages of the traits spike diameter (SD), spike length (SL), number of rows with grains per spike (NRG), number of grains per row (NGR), spike mass (SM), cob diameter (CD), cob mass (CM), mass of a thousand grains (MTG), mass of grains per spike (MGS) and grain yield (GY) for the source of variation three-waycross maize hybrids

The variation source growing environments (Table 3) revealed significant differences for the traits spike diameter (SD), number of grains per row (NGR), spike mass (SM), cob diameter (CD), cob mass (CM), mass of a thousand grains (MTG), mass of grains per spike (MGS) and grain yield (GY).

The hybrid KSP 3248 presented the highest magnitude for the traits SD, SL, SM, CM, MTG and MGS, differing from the hybrid 2A55Hx[®] for SD, from the hybrids 2A55Hx, 2B688Hx[®] and AG8011 for SL, from the hybrids DKB566VTPRO[®] and AG8011 for CM, and from the hybrid 2A55Hx[®] for MGS. The hybrid 2B688Hx[®] presented the highest magnitude for the trait NRG, statistically differing from the hybrids DKB566VTPRO[®] and KSP3248[®].

The growing environment of Campos Borges, RS presented positive influence for incrementing grain yield of the evaluated three-way cross maize hybrid.

Table 3. Averages of the traits spike diameter (SD), spike length (SL), number of rows with grains per spike (NRG), number of grains per row (NGR), spike mass (SM), cob diameter (CD), cob mass (CM), mass of a thousand grains (MTG), mass of grains per spike (MGS) and grain yield (GY) for the source of variation growing environment

These differentiations may occur due to variation in altitude between environments, thermal amplitude, energy balance, light quality on the crop canopy, and soil and climatic conditions. Elevated temperatures during the night promote higher energetic consumption due to the increment of cellular respiration, resulting in lower balance of photoassimilates and consequently, reducing grain yield (Fancelli & Dourado Neto, 2000; Carvalho et al., 2016).

Regarding the trait PH (Table 4), the hybrid 2B339Hx[®] was superior in the growing environment of Campos Borges-RS. In the environment of Salto do Jacuí-RS, the hybrids 2B339Hx[®], 2B688Hx[®] and AG8011[®] were superior. This differential behavior is explained because plant height is a quantitative trait controlled by many genes, with elevated influence of the environment on phenotype and being highly dependent of management techniques, population density (Abuzar et al., 2011; Szarecki et al., 2017), cycle duration, as early genotypes may express shorter plants (Cruz et al., 2010). Spike insertion height (Table 4) is closely related to losses in mechanic harvest, therefore, uniformity of this trait is essential for an efficient mechanic harvest. Li et al. (2007) affirm that high values of spike insertion height strongly contribute for lodging in maize field. In the environment of Campos Borges-RS, the hybrid 2B339Hx[®] was superior to the others, however, in the growing environment of Salto do Jacuí-RS, the superior genotypes were DKB566VTPRO[®], 2A55Hx[®] and 2B688Hx[®].

There were no differences among genotypes for the trait Prolificity (PRO) (Table 4) in the growing environment of Campos Borges-RS. However, in the growing environment of Salto do Jacuí-RS, the hybrid 2A55Hx[®] reduced this trait in 27%. Prolific plants are generally more tolerant to adverse conditions due to their plasticity under stress situations, and may positively influence grain yield when population density is below the ideal (Sangoi et al., 2010). The optimization of number of grains per unity of area is possible through the increment of populational density and the number of spikes per plant, depending on the genotype's genetic base (Lopes et al., 2007; Szareski et al., 2016).

The Pearson's linear correlation performed for 13 traits revealed 78 associations, of which 43 were significant (Table 5). Correlation is a statistic estimator that measures the level of association between two variables. Thereby, correlated traits occur when a variation in one trait is followed by a simultaneous variation in the other (Ramalho et al., 2012). The knowledge about phenotypic, genetic and environment correlation is essential for simultaneous selection of more than one trait, or when the character of interest presents low heritability or is difficult to be measured (Falconer & Mackay, 1996).

The trait PH is strongly and positively correlated with SH ($r = 0.75$) due to the tendency of spike height to variate in accordance to plant height. Thus, higher plants tend to have spikes farther from the soil surface. The trait SH presents moderate and positive correlation with SD ($r = 0.45$), SM ($r = 0.39$), CM ($r = 0.35$), MTG ($r = 0.41$), MG ($r = 0.44$) and GY ($r = 0.46$), being a morphological trait that possible may be used in indirect selection of grain yield components. The trait SD presented strong and positive correlation with SM ($r = 0.86$), CM ($r = 0.85$), MTG ($r = 0.86$), MG ($r = 0.90$), CD ($r = 0.73$) and GY ($r = 0.62$), and moderate and positive correlations with SL ($r = 0.37$) and NGR ($r = 0.43$). Thus, plants with wider spikes tend to present increment in several grain yield components, such as mass of grains per spike and mass of a thousand grains, and consequently, greater grain yield. The trait SL evidenced strong and positive correlation with NGR ($r = 0.78$), moderate and positive with SM ($r = 0.57$), CM ($r = 0.53$), MTG ($r = 0.46$) and MG ($r = 0.59$). Plants with longer spikes tend to present higher number of grains per row, thus, spikes with more grains, resulting in an increment of cob and spike mass.

Table 5. Estimates of Pearson's linear correlation for the traits plant height (PH), spike insertion height (SH), prolificity (PRO), spike diameter (SD), spike length (SL), number of rows with grains per spike (NRG), number of grains per row (NGR), spike mass (SM), cob diameter (CD), cob mass (CM), mass of a thousand grains (MTG), mass of grains per spike (MGS) and grain yield (GY)

Note. * Significant values at 5% of probability; ** Significant values at 1% of probability.

The trait NGR correlated moderately and positively with SM ($r = 0.57$), CM ($r = 0.43$) and MTG ($r = 0.48$), and strongly and positively with MG ($r = 0.67$), however it presented correlation of weak and positive magnitude with GY ($r = 0.34$). Spikes with more grains per row tend to be longer, presenting greater mass of grains, incrementing grain yield. Number of grains per row is the yield component that most contribute for grain yield in maize open pollinated varieties. However, prolificity, number of rows with grains per spike and mass of grains are determinant for grain yield (Balbinoti Junior et al., 2005).

The trait SM presented very strong and positive correlation with CM ($r = 0.89$), MTG ($r = 0.88$), MG ($r = 0.92$), and moderate and positive with CD ($r = 0.64$) and GY ($r = 0.52$). Spike mass is given by the sum of spike grains mass and cob mass, justifying the positive relation evidenced for these components. Performing similar study, Lopes et al. (2007) verified that mass of grains per spike is positively correlated with eight of the nine explanatory variables. Besides, 75% of the explanatory variables are positively correlated among themselves, evidencing the complexity of relations in maize spike traits. This fact implies the difficulty of selecting maize genotypes because it jeopardizes the identification of characteristics of more interest. Therefore, the ideal procedure was to slice correlations in direct and indirect effects in order to evaluate the degree of importance of each explanatory trait on the dependent variable (Daros et al., 2004; Ferrari et al., 2016).

The interest on evaluating the relative contribution of traits for diversity lays on the possibility to discard characters which poorly contribute to discriminate the genotypes, reducing labor, time and money spent on experimentation (Rotili et al., 2012; Nardino et al., 2017). The dispensable traits in studies of genetic divergence are those with few variations among genotypes, or redundant for being correlated with other traits, such as plant height and spike height, which commonly are measured in maize breeding programs (Miranda et al. 2003). In this study, the evaluated traits (Table 5) SH (20.083%), SD (18.373%), PH (14.414%), MTG (10.887%) presented the higher percentages of contributions, confronting the previous affirmation. Analyzing maize genotypes, Silva and Peluzio (2014) concluded that traits with higher contribution for divergence were plant height (24.63%), plant green mass (10.28%), spike diameter (11.32%) and number of grains per row (9.11%), totalizing 55.34% of contribution. In the three-way cross maize hybrids evaluated, it is suggested to discard CD (1.225%), PRO (1.454%), CB (2.035%), NGR (3.412%) and MG (3.367%) due to their low percentage of contribution for genotypes' discrimination.

The canonical variates analysis is an alternative procedure to evaluate the degree of similarity among hybrids, considering both the residual covariance matrix and the covariance between phenotypic means of the evaluated traits. This technique is based on a large number of correlated original characteristics, achieving linear combinations in such way the correlation between them is null (Kendall, 1950). Hence, Table 6 and Figure 1 represents the grouping of six three-waycross maize hybrids for the 13 measured traits.

Table 6. Relative contribution for diversity of six three-way cross maize hybrids in two growing environments by Singh (1981), considering the following traits: plant height (PH), spike insertion height (SH), prolificity (PRO), spike diameter (SD), spike length (SL), number of rows with grains per spike (NRG), number of grains per row (NGR), spike mass (SM), cob diameter (CD), cob mass (CM), mass of a thousand grains (MTG), mass of grains per spike (MGS) and grain yield (GY)

Trait	S.J	Value (%)
PH	93.64	14.41
SH	130.47	20.08
PRO	9.44	1.45
SD	119.36	18.37
SL	62.34	9.56
NRG	37.72	5.80
NGR	22.17	3.41
SM	38.31	5.89
CD	7.96	1.22
CM	13.22	2.03
MTG	70.73	10.88
MGS	21.87	3.36
GY	22.37	3.44

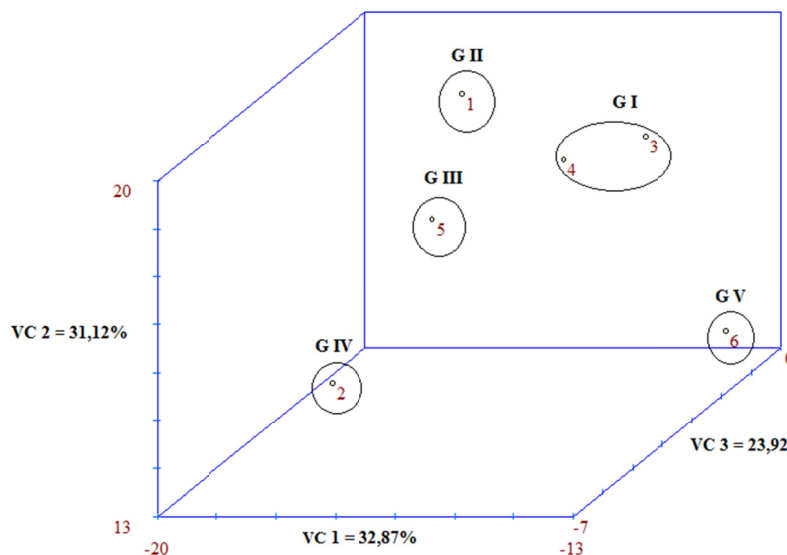

Figure 1. Graphic representation of the canonical variates obtained through evaluation of thirteen traits of agronomic interest in six three-way cross maize hybrids, where, 1 = DKB566VTPRO[®]; 2 = 2B339HX[®]; 3 = 2A55HX[®]; 4 = 2B688HX[®]; 5 = AG8011[®]; 6 = KSP3248[®]

The hybrids 2B688Hx[®] and 2A55Hx[®] were arranged in the same group of canonical variates (group I). The means observed for these genotypes are similar. Therefore, the phenotypic similarity evidenced is due to germplasm from the same breeder, and there might be a degree of relatedness between their parent lineages. The other genotypes were organized in four distinct groups because of their phenotypic differences.

4. Conclusion

The three-way cross maize hybrids evaluated evidence phenotypic variability for the traits spike diameter, spike length, number of rows with grains, number of grains per row, cob mass and spike grains mass.

The growing environment of Campos Borges-RS favors the increment of spike diameter, number of grains per row, spike mass, cob diameter, cob mass, mass of a thousand grains, spike grains mass and grain yield. Significant interactions between three-way cross maize hybrids and growing environments are verified for plant height, spike insertion height and prolificity.

The traits spike diameter, mass of a thousand grains and mass of grains per spike present positive correlation with maize grain yield.

The distinction of three-way cross hybrids is based on spike insertion height, spike diameter, plant height and mass of a thousand grains. The hybrids 2B688 HX[®] and 2A55 HX[®] are genetically closer, according to the biometric approach of canonical variables.
